Session: Business Systems

Topic: Databases

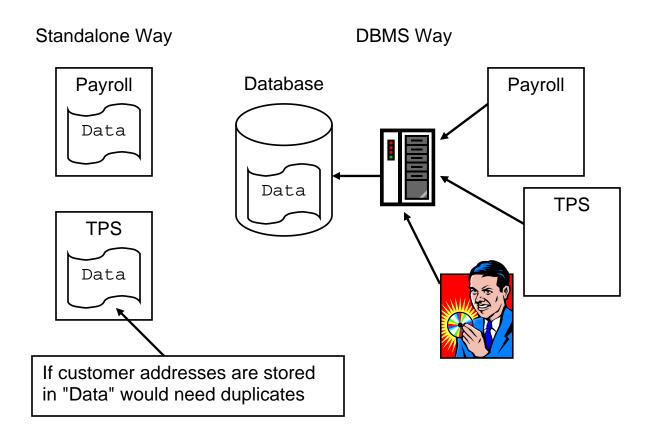

Daniel Chang

Data Management

- Business organizations must manage data from many sources
- Data comes from Business Information Systems (such as a TPS)

Database Management Systems

- The actual thing that stores data is the "Database"
- A Database Management System (DBMS) is the front end to the database that provides access to the database
- Other software applications and users go through the DBMS rather than touch the database directly
- This is in contrast to a standalone software program that keeps its own data as part of the program

Database Advantages

- Allows data to be located in one place instead of duplicated (data redundancy)
- Allows data to be easily shared
- Ensures data is organized and maintained according to rules of DBMS
- Help to ensure that stored information is correct (data integrity). Avoiding data redundancy helps
- Simplifies access to database (DBMS provides interface)
- Allows DBMS, as single point of access, to secure data

Data Organization

Fields

- Usually the smallest piece of information
- Field itself is given a "field name", field then contains actual "values"
- Fields can often be "typed", or restricted to certain kinds of values ("numeric only", "date format")
- Intended to represent an "Attribute" of some larger object
- Example: "LastName", "PhoneNumber"

Records

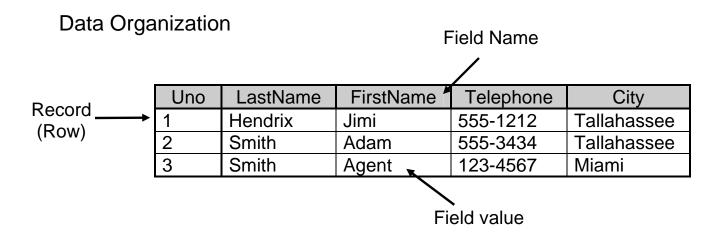

- Contains fields
- Intended to be fields that together describe some object, or "Entity"
- Often each record will have a field that is a unique identifier, or "Primary Key" to individually identify each record
 - Sometimes called an "Uno"
 - Can be a meaningful field (such as "EmployeeID") or simply a unique number
- Example: "Customer" records contain "LastName", "PhoneNumber", "Address"

Tables (Files)

- Contains a bunch of record
- Usually represented in a grid like a spreadsheet

Database

Collection of tables

In the Database...

- "Entities" are represented by "Records"
- "Attributes" that describe some feature of an "Entity" are represented by "Fields"

Relational Databases

- Method for organizing data in database by using tables
- Tables are related to each other through their Primary Keys
- That is, fields in one table may contain Primary Keys of other tables as their value to relate a record to another record
- A field that contains the primary key from another table is called a "Foreign Key" field

Customers (Table)

| Uno | LastName | FirstName | Telephone | AddressUno |
|-----|----------|-----------|-----------|------------|
| 1 | Hendrix | Jimi | 555-1212 | 5 |
| 2 | Smith | Adam | 555-3434 | 3 |
| 3 | Smith | Agent | 123-4567 | 4 |

| | Uno | Street | City | State | Zip |
|-------------------|-----|--------------|-------------|---------|-------|
| \longrightarrow | 3 | 1 Main St. | Tallahassee | Florida | 33333 |
| | 4 | 9 First Ave. | Miami | Florida | 33331 |
| | 5 | Easy Street | Butte | Montana | 33313 |

Addresses (Table)

Relation Types

- A "one-to-many" relationship is more common, where one record in a table can relate to multiple records in another
- For example, an "Invoices" table may have many entries for a single "Customer"

Invoices (Table)

| Uno | CustomerUno | Item | Qty | Date |
|-----|-------------|-----------|-------|------------|
| 3 | 2 | Widgets | 200 | 10/10/20XX |
| 4 | 2 | Sprockets | 50 | 9/10/20XX |
| 5 | 3 | Widgets | 10000 | 10/10/20XX |
| | | | | |

Same "Customer" can be related to multiple "Invoices" rows

- Above "Customers" to "Addresses" relationship could be made one-to-many with some modifications
- Would "one" customer typically have "many" addresses?
- A "many-to-many" relationship really means your data organization needs some analysis, possibly using an intermediate table

Relation Example

Database Access

- Relational database organization allows information to be "filtered" when retrieved
- That is, only records that satisfy a given criteria are returned
- Example: "Only records with "LastName" field having value "Smith"
- Most databases have a special language for "querying" the database for data
- "Structured Query Language" (SQL) is the most common

SQL Examples

 Get entire record from "CustomerInfo" table for all records with a LastName value of "Smith"

```
select * from Customers where LastName =
Smith
```

 Get only "Telephone" field value from "CustomerInfo" table for Adam Smith

```
select Telephone from Customers where
LastName = "Smith" AND FirstName = "Adam"
```

 Get all LastName and City for every record ("Join" two tables)

```
select Customers.LastName, Addresses.City
from Customers, Addresses where
Customers.AddressUno = Addresses.Uno
```

Database Design

Schema

- A "Schema" is a formal definition of how data in a database is structured and how tables are related to each other
- DBMS can often use a schema written in a "Data Definition Language" (UML, XSL) to generate tables and find data

Data Dictionary

- Typically describes things such as table names, the exact field names contained in each table, and the field types
- Often stored within the database itself and used by programs to find out what kind of data they are accessing
- For example, can be used to determine the "type" of a particular field

Some Interesting Database Uses

Data Warehouse

- A really big database
- Typically tracks a lot of transactions
- Example: Wal-Mart data warehouse has details of every receipt for the past 10 years (or so). The database is half a PetaByte (500 TeraBytes, or 500,000 GigaBytes)
- Allows analysis of trends (what sells most at what times, etc.)

Data Mining

- You can request specific information you want from a large data store
- But Data Mining analyzes the data store to find information filters you have never thought to look for
- In 1992 Teradata analyzed a retailer's sales data warehouse and discovered that in the evening hours "beer" and "diapers" are frequently purchased together (an affinity)
- Incidentally, Teradata maintains Wal-Mart's data warehouse
- Wal-Mart placed beer next to diapers, with potato chips in between and increased sales of all three

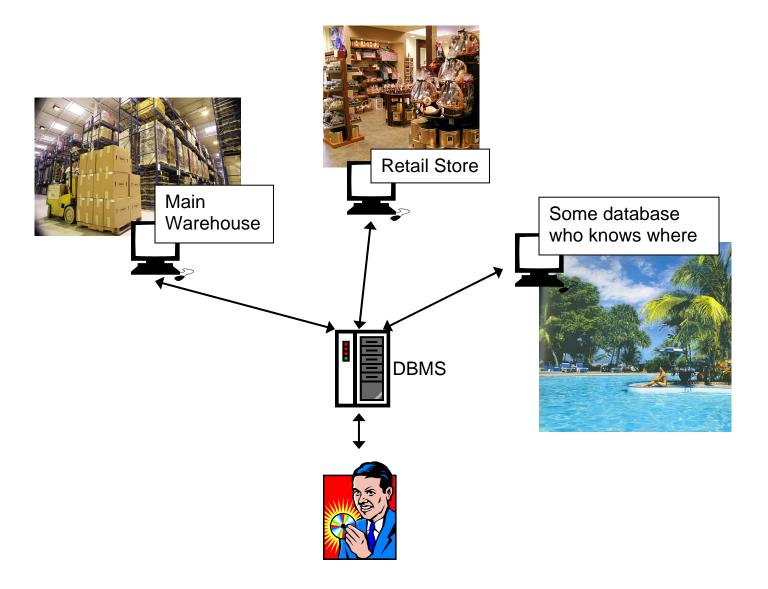

Distributed Database

- Actual data is spread across several separate databases
- DBMS makes it appear to be one collection of data by providing central point for access
- Lends itself to connecting databases over the Internet

Employment

- Databases are critical to business organizations
- Database management is a huge task
- Jobs include Database Administrators and development of software programs / web-based programs to access databases
- But almost all employees of significance will have to access the database

Business Systems

- Almost all systems will access the organizational database
- TPS put data in
- MIS pulls data out and reports it
- DSS, ES pulls data out, uses it and reports it
